

Accelerating Exact k -means Algorithms with Geometric Reasoning

Dan Pelleg and Andrew Moore

Abstract

We present new algorithms for the k -means clustering problem. They use a new kind of kd -tree traversal algorithm supplemented with a novel pruning test to give sublinear cost both in the number of datapoints and in the number of centers. The kd -trees are decorated with extra “cached sufficient statistics” as in [3]. Sufficient statistics are stored in the nodes of the kd -tree. Then, an analysis of the geometry of the current cluster centers results in great reduction of the work needed to update the centers. Our algorithms behave exactly as the traditional k -means algorithm. Proofs of correctness are included. The kd -tree can also be used to initialize the k -means starting centers efficiently. Our algorithms can be easily extended to provide fast ways of computing the error of a given cluster assignment, regardless of the method in which those clusters were obtained. We also show how to use them in a setting which allows approximate clustering results, with the benefit of running faster.

We have implemented and tested our algorithms on both real and simulated data. Results show a speedup factor of up to 170 on real astrophysical data, and superiority over the naive algorithm on simulated data in up to 5 dimensions. Our algorithms scale well with respect to the number of points and number of centers, allowing for clustering with tens of thousands of centers.

1 Introduction

Given a dataset and a constant k , the *clustering* problem is to partition the data into k subsets such that each subset behaves “well” under some measure. For example, we might want to minimize the squared Euclidean distances between points in any subset and their center of mass. The k -means algorithm for clustering finds a local optimum of this measure by

keeping track of centroids of the subsets, and issuing a large number of nearest-neighbor queries [6].

A kd -tree is a data structure for storing a finite set of points from a finite-dimensional space [1]. Recently, Moore has shown its usage in very fast EM-based Mixture Model Clustering [8]. The need for such a fast algorithm arises when conducting massive-scale model selection, and in datasets with a large number of attributes and records (see also [9]).

We show that kd -trees can be used to reduce the number of nearest-neighbor queries in k -means by using the fact that their nodes can represent a large number of points. We are frequently able to prove for certain nodes of the kd -tree statements of the form “any point associated with this node must have X as its nearest neighbor” for some center X . This, together with a set of statistics stored in the kd -nodes, allows for great reduction in the number of arithmetic operations needed to update the centroids of the clusters.

We have implemented our algorithms and tested their behavior with respect to variations in the number of points, dimensions, and centers, as measured on synthetic data. We also present results of tests on preliminary SDSS data.

The remainder of this paper is organized as follows. In Section 2 we discuss related work, introduce notation and describe the naive k -means algorithm. In Section 3 we present our algorithms with proofs of correctness. Section 4 discusses results of experiments on real and simulated data, and Section 5 concludes and suggests ideas for further work.

2 Definitions and Related Work

Throughout this paper, we denote the number of records by R , the number of dimensions by M and the number of centers by k .

We first describe the naive k -means algorithm for producing a clustering of the points in the input into k clusters. It is the best known of all clustering algorithms, and literally hundreds of papers about its theory and deployment have appeared in the statistics

literature in the last 20 year [4, 2]. The algorithm partitions the data-points into k subsets such that all points in a given subset “belong” to some center. The algorithm keeps track of the centroids of the subsets, and proceeds in iterations. We denote the set of centroids after the i -th iteration by $C^{(i)}$. Before the first iteration the centroids are initialized to random values. The algorithm terminates when $C^{(i)}$ and $C^{(i-1)}$ are identical. In each iteration, the following is performed:

1. For each point x , find the center in $C^{(i)}$ which is closest to x . Associate x with this center.
2. Compute $C^{(i+1)}$ by taking, for each center, the center of mass of points associated with this center.

Our algorithms involve modification of just the code within one iteration. We therefore analyze the cost of a single iteration. Naive k -means performs a “nearest-center” query for each of the R points. During such a query the distances in M -space to k centers are calculated. Therefore the cost is $O(kMR)$.

One fundamental tool we will use to tackle the problem is the kd -tree data-structure. A thorough discussion is out of the scope of this paper. We just outline its relevant properties, and from this point on will assume that a kd -tree for the input points exists. Further details about kd -trees can be found in [7]. We will use a specialized version of kd -trees called *mrkd*-trees, for “multi-resolution kd -trees” [3]. Their properties are:

- They are binary trees.
- Each node contains information about all points contained in a hyper-rectangle h . The hyper-rectangle is stored at the node as two M -length boundary vectors h^{\max} and h^{\min} . At the node are also stored the number, center of mass, and sum of Euclidean norms, of all points within h . All children of the node represent hyper-rectangles which are contained in h .
- Each non-leaf node has a “split dimension” d and a “split value” v . Its children l (resp. r) represent the hyper-rectangles h_l (h_r), both within h , such that all points in h_l (h_r) have their d -th coordinate value smaller than (at least) v .
- The root node represents the hyper-rectangle which encompasses all of the points.
- Leaf nodes store the actual points.

For two points x, y we denote by $d(x, y)$ their Euclidean distance. For a point x and a hyper-rectangle h we define $\text{closest}(x, h)$ to be the point in h which is closest to x . Note that computing $\text{closest}(x, h)$ can be done in time $O(M)$ due to the following facts:

- If $x \in h$, then x is closest.
- Otherwise, $\text{closest}(x, h)$ is on the boundary of h . This boundary point can be found by clipping each coordinate of x , to lie within h , as shown in [7].

We define the distance $d(x, h)$ between a point x and a hyper-rectangle h to be $d(x, \text{closest}(x, h))$. For a hyper-rectangle h we denote by $\text{width}(h)$ the vector $h^{\max} - h^{\min}$.

Given a clustering ϕ , we denote by $\phi(x)$ the centroid this clustering associates with an arbitrary point x (so for k -means, $\phi(x)$ is simply the center closest to x). We then define a measure of quality for ϕ :

$$\text{distortion}_\phi = \frac{1}{R} \cdot \sum_x d^2(x, \phi(x)) \quad (1)$$

where R is the total number of points and x ranges over all input points.

The k -means algorithm is known to stop at a local minimum of the distortion measure. It is also known to be too slow for practical databases. Much of the related work does not attempt to confront the algorithmic issues directly. Instead, different methods of subsampling and approximation are proposed. A way to obtain a small “balanced” sample of points by sampling from the leaves of a R^* tree is shown in [5]. In [10], a simulated-annealing approach is suggested to direct the search in the space of possible partitions of the input points. A tree structure with sufficient statistics is presented in [12]. It is used to identify outliers and speed computations. However, the calculated clusters are approximations, and depend on many parameters.

3 Algorithms

Our algorithms exploit the fact that instead of updating the centroids point by point, a more efficient approach is to update in bulk. This can be done using the known centers of mass and size of groups of points. Naturally, these groups will correspond to hyper-rectangles in the kd -tree. To ensure correctness, we must first make sure that all of the points in a given rectangle indeed “belong” to a specific center before adding their statistics to it. This gives rise to the notion of an *owner*.

Definition 1 *Given a set of centers C and a hyper-rectangle h , we define by $\text{owner}_C(h)$ a center $c \in C$ such that any point in h is closer to c than to any other center in C , if such a center exists.*

We will omit the subscript C where it is clear from the context. The rest of this section discusses owners and efficient ways to find them. We start by analyzing a property of owners, which, by listing those centers

Figure 1: Domination with respect to a hyper-rectangle. L_{12} is the decision line between centers c^1 and c^2 . Similarly, L_{13} is the decision line between c^1 and c^3 . p_{12} is the extreme point in h in the direction $c^2 - c^1$, and p_{13} is the extreme point in h in the direction $c^3 - c^1$. Since p_{12} is on the same side of L_{12} as c^1 , c^1 dominates c^2 with respect to the hyper-rectangle h . Since p_{13} is not on the same side of L_{13} as c^1 , c^1 does not dominate c^3 .

which do not have it, will help us eliminate non-owners from our set of possibilities. Note that $\text{owner}_C(h)$ is not always defined. For example, when two centers are both *inside* a rectangle, then there exists no unique owner for this rectangle. Therefore the precondition of the following theorem is that there exists a unique owner. The algorithmic consequence is that our method will not always find an owner, and will sometimes be forced to descend the kd -tree, thereby splitting the hyper-rectangle in hope to find an owner for the smaller hyper-rectangle.

Theorem 2 *Let C be a set of centers, and h a hyper-rectangle. Let $c \in C$ be $\text{owner}_C(h)$. Then:*

$$d(c, h) = \min_{c' \in C} d(c', h) .$$

Proof: Assume, for the purpose of contradiction, that $c \neq \arg \min_{c' \in C} d(c', h) \equiv c'$. Then there exists a point in h (namely $\text{closest}(c', h)$) which is closer to c' than to c . A contradiction to the definition of c as $\text{owner}(h)$. \square

Equivalently, we can say that when looking for $\text{owner}(h)$, we should only consider centers with shortest (as opposed to “minimal”) distance $d(c, h)$. Suppose that two (or more) centers share the minimal distance to h . Then neither can claim to be an owner.

Theorem 2 narrows down the number of possible owners to either one (if there exists a shortest distance center) or zero (otherwise). In the latter case, our algorithm will proceed by splitting the hyper-rectangle. In the former case, we still have to check if this candidate is an owner of the hyper-rectangle in question. As will become clear from the following discussion, this will not always be the case. Let us begin by defining a restricted form of ownership, where just two centers are involved.

Definition 3 *Given a hyper-rectangle h , and two centers c^1 and c^2 such that $d(c^1, h) < d(c^2, h)$, we say that c^1 dominates c^2 with respect to h if every point in h is closer to c^1 than it is to c^2 .*

Observe that if some $c \in C$ dominates *all* other centers with respect to some h , then $c = \text{owner}(h)$. A possible (albeit inefficient) way of finding $\text{owner}(h)$ if one exists would be to scan all possible pairs of centers. However, using theorem 2, we can reduce the number of pairs to scan since c^1 is fixed. To prove this approach feasible we need to show that the domination decision problem can be solved efficiently.

Lemma 4 *Given two centers c^1, c^2 , and a hyper-rectangle h such that $d(c^1, h) < d(c^2, h)$, the decision problem “does c^1 dominate c^2 with respect to h ?” can be answered in $O(M)$ time.*

Proof: Observe the decision line L composed of all points which are equidistant to c^1 and c^2 (see Figure 1). If c^1 and h are both fully contained in one half-space defined by L , then c^1 dominates c^2 . The converse is also true; if there exists a point $x \in h$ such that it is not in the same half-space of L as c^1 , then $d(c^1, x) > d(c^2, x)$ and c^1 does not dominate c^2 . It is left to show that finding whether c^1 and h are contained in the same half-space of L can be done efficiently. Consider the vector $\vec{v} \equiv c^2 - c^1$. Let p be a point in h which maximizes the value of the inner product $\langle \vec{v}, p \rangle$. This is the extreme point in h in the direction \vec{v} . Note that \vec{v} is perpendicular to \vec{L} . If p is closer to c^1 than it is to c^2 , then so is any point in h (p is the closest one can get to L , within h). If not, p is a proof that c^1 does not dominate c^2 .

Furthermore, the linear program “maximize $\langle \vec{v}, p \rangle$ such that $p \in h$ ” can be solved in time $O(M)$. Again we notice the extreme point is a corner of h . For each coordinate i , we choose p_i to be h_i^{\max} if $c_i^2 > c_i^1$, and h_i^{\min} otherwise. \square

3.1 The Simple Algorithm

We now describe a procedure to update the centroids in $C^{(i)}$. It will take into consideration an additional parameter, a hyper-rectangle h such that all points in

h affect the new centroids. The procedure is recursive, with the initial value of h being the hyper-rectangle with all of the input points in it. If the procedure can find $\text{owner}(h)$, it updates its counters using the center of mass and number of points which are stored in the kd -node corresponding to h (we will frequently interchange h with the corresponding kd -node). Otherwise, it splits h by recursively calling itself with the children of h . The proof of correctness follows from the discussion above.

Update(h, C):

1. If h is a leaf: For each data point in h , find the closest center to it and update that center's counters. Return.
2. Compute $d(c, h)$ for all centers c . If there exists one center c with shortest distance:

If for all other centers c' , c dominates c' with respect to h :

Update c 's counters using the data in h .
Return.

3. Call $\text{Update}(h_l, C)$.
4. Call $\text{Update}(h_r, C)$.

We would not expect our Update procedure to prune in the case that h is the universal set of all input points (since all centers are contained in it, and therefore no shortest-distance center exists). We also notice that if the hyper-rectangles were split again and again so that the procedure is dealing just with leaves, this method would be identical to the original k -means. In fact, this implementation will be much more expensive because of the redundant overhead. Therefore our hope is that large enough hyper-rectangles will be owned by a single center to make this approach worthwhile. See Figure 2 for a visualization of the procedure operation.

3.2 The “Blacklisting” Algorithm

Our next algorithm is a refinement of the simple algorithm. The idea is to identify those centers which will definitely *not* be owners of the hyper-rectangle h . If we can show this is true for some center c , there is no point in checking c for any of the descendants of h , hence the term “blacklisting”. Let c^1 be a minimal-distance center to h , and let c^2 be any center such that $d(c^2, h) > d(c^1, h)$. If c^1 dominates c^2 with respect to h , we have two possibilities. One, that $c^1 = \text{owner}(h)$. This is the good case since we do not need any more computation. The other option is that we have no owner for this node. The slow algorithm would have given up at this point and restarted a computation for the children of h . The blacklisting version notices that c^1 dominates c^2 with respect to h' for any h' contained in h . This is true by definition. Now, since the

Figure 2: Visualization of the hyper-rectangles owned by centers. The entire two-dimensional dataset is drawn as points in the plane. All points that “belong” to a specific center are colored the same color (here, $K=2$). The rectangles for which it was possible to prove that belong to specific centers are also drawn. Points outside of rectangles had to be determined in the slow method (by scanning each center). Points within rectangles were not considered by the algorithm. Instead, their number and center of mass are stored together with the rectangle and are used to update the center coordinates.

descendants of h in the kd -tree are all contained in h , we can eliminate c^2 from the list of possible centers at this point for all descendants. Thus the list of prospective owners shrinks until it reaches a size of 1. At this point we declare the only remaining center the owner of the current node h . Again, we hope this happens before h is a leaf node, otherwise our overhead is wasted.

3.3 Efficiently Computing Goodness-Of-Fit Statistics

As an added bonus, the “ownership” property can help accelerate other computations. With the small price of storing, in each kd -node, the sum of the squared norms of all points of this node, one can use the exact same algorithm to compute the distortion measure defined in Equation 1. We omit the straightforward algebra. For other obtainable statistics see [12].

4 Experimental Results

We have conducted experiments on both real and randomly-generated data. The real data is preliminary SDSS data with some 400,000 celestial objects. The synthetic data covers a wide range of parameters that might affect the performance of the algorithms. Some of the measures are comparative, and measure the

performance of our algorithms against both the naive algorithm and BIRCH [12]. Others simply test our fast algorithms' behavior on different inputs. Due to space constraints, the details are omitted. The interested reader may find them at [11].

4.1 Approximate Clustering

Another way to accelerate clustering is to prune the search when only small error is likely to be incurred. We do this by not descending down the kd -tree when a "small-error" criterion holds for a specific node. We then assume that the points of this node are divided evenly among all current competitors. For each such competing center c , we update its location as if the relative number of points are all located at $\text{closest}(c, h)$. Our pruning criterion is:

$$n \cdot \sum_{j=1}^M \left(\frac{\text{width}(h)_j}{\text{width}(U)_j} \right)^2 \leq d^i$$

where n denotes the number of points in h , U is the "universal" hyper-rectangle bounding all of the input points, i is the iteration number, and d is a constant, typically set to 0.8. For experimental results for this heuristic, see [11].

5 Conclusion

The main message of this paper is that the well-known k -means algorithm need not be considered an impractically slow algorithm, even with many millions of records. We have described, analyzed and given empirical results for a new fast implementation of k -means. We have shown how a kd -tree of all the datapoints, decorated with extra statistics, can be traversed with a new, extremely cheap, pruning test at each node. Another new technique—blacklisting—gives a many-fold additional speed-up, both in theory and empirically.

For datasets too large to fit in-core, the same traversal and black-listing approaches could be applied to an on-disk structure such as an R -tree, permitting tractable, exact k -means even for many billions of records.

This method performs badly in high (> 8) dimensions: it is not a clustering panacea, but possibly a worthy problem-specific tool for domains in which there is massively large amounts of low-dimensional data (e.g. astrophysics, geospatial data, and controls). We are also investigating whether AD-trees [9] could be used to give similar speed-ups on categorical data: an advantage of AD-trees is that, subject to many caveats, they remain efficient up to hundreds of dimensions.

Unlike previous approaches (eg., $mrkd$ -trees for EM [8]) this new algorithm scales very well with the number of centers, permitting clustering with tens of thousands of centers. Why would we care about making exact

k -means fast? Why not just use a fast non- k -means approximate clusterer? First, exact k -means is a well-established algorithm that has prospered for many years as a clustering algorithm workhorse. Second, it is often used to help find starting clusters for more sophisticated iterative methods such as mixture models. Third, running k -means on an in-memory sample of the points is a popular approximate clustering algorithm for monstrously large datasets. The techniques in this paper can make such preprocessing steps efficient. Finally, with fast k -means, we can afford to run the algorithm many times in the time it would usually take to run it once. This allows automatic selection of k , or subsets of attributes upon which to cluster, to become a tractable, real-time operation.
